Abstract.
The Solar Mean Magnetic Field (SMMF) is the mean value of the line-of-sight (LOS) component of the solar vector magnetic field averaged over the visible hemisphere of the Sun. So far, the studies on SMMF have mostly been confined to the magnetic field measurements at the photosphere. In this study, we calculate and analyse the SMMF using magnetic field measurements at the chromosphere, in conjunction with that of photospheric measurements. For this purpose, we have used full-disk LOS magnetograms derived from spectropolarimetric observations carried out in Fe I 6301.5 Å and Ca II 8542 Å by the Synoptic Optical Long-term Investigations of the Sun (SOLIS)/Vector Spectromagnetograph (VSM) instrument during 2010 – 2017. It is found from this study that the SMMF at the chromosphere is weaker by a factor of 0.60 compared to the SMMF at the upper-photosphere. The correlation analysis between them gives a Pearson correlation coefficient of 0.80. The similarity and reduced intensity of the chromospheric SMMF with respect to the photospheric SMMF corroborate the idea that it is the source of the Interplanetary Magnetic Field (IMF).

Keywords. solar magnetic field – chromospheric field – disk-averaged field – SMMF – mean field – response function

1. Introduction

The Solar Mean Magnetic Field (SMMF) is the disk averaged value of the line-of-sight (LOS) magnetic field of the Sun. It is also known as General Magnetic Field (GMF), Sun as a Star Magnetic Field (SSMF), Mean Magnetic Field (MMF) and global magnetic field, among others. George Ellery Hale, who discovered magnetic fields on the Sun (Hale, 1908), was also the first to study the global magnetic field of the Sun (Hale, 1913). A summary of the measurements of the global magnetic field of the Sun, carried out till the 1960s, is given in Severny (1964).

A number of studies have been done since then on the SMMF, particularly on the properties of the SMMF, its origin and its effects on the interplanetary magnetic field (IMF), which is the magnetic field in interplanetary space (Wilcox & Ness, 1965; Severny, 1969; Severny *et al.*, 1970; Severny, 1971; Scherrer *et al.*, 1972; Svalgaard, 1972; Svalgaard *et al.*, 1975; Scherrer *et al.*, 1977a; Kotov & Levitsky, 1983; Hoeksema & Scherrer, 1984; Sheeley & DeVore, 1986; Demidov & Grigoryev, 1998; Kotov *et al.*, 1998; Demidov *et al.*, 2002; Hudson *et al.*, 2014; Sheeley & Wang, 2014; Sheeley & Wang, 2015; Sheeley, 2022). These studies have es-

tablished the magnitude and periodicity of the SMMF. They have shown that the SMMF has a non-zero value and a prominent periodicity of ≈ 27 days. Its amplitude changes from $\approx \pm 0.2$ gauss during the solar minima to $\approx \pm 2$ gauss during the solar maxima (Plachinda *et al.*, 2011).

On the other hand, a lot of uncertainty exists regarding the origin of the SMMF. There is a possibility that the SMMF could be the remnant dipolar component of the primordial magnetic field present in the protostellar cloud during the formation of the Sun. The argument for this goes as follows. Gough & McIntyre (1998) established the necessity of having a large-scale magnetic field in the radiative zone of the Sun. Later, Gough (2017) provided supporting arguments for a part of this interior magnetic field to emerge to the surface, where we could observe it as the SMMF. The very good correlation of the SMMF with the IMF augments this possibility. On the other hand, Kutsenko *et al.* (2017) explained the SMMF as a result of the rotational modulation of high-intensity active region fields, and Ross *et al.* (2021) brought forward evidence that supported the connection of the rotationally modulated component of the SMMF to strong field regions like active regions and magnetic flux concentrations. However, on

the same topic, Bose & Nagaraju (2018) divided the solar surface into different features with the aid of image recognition and showed a high degree of correlation between the SMMF and the background solar field (and very little correlation between the SMMF and the field from active regions).

A comparison of the SMMF observed by different instruments was carried out by Demidov (2000). Since then, comparisons of SMMF derived from the observations of different instruments (both space-borne and ground-based) have been done by many authors. A good overview of these inter-instrument comparisons and references to earlier works are given in Pietarila *et al.* (2013) and Riley *et al.* (2014). These have largely been comparisons of disk-resolved magnetograms. In Pietarila *et al.* (2013), both disk-resolved and SMMF comparisons are made, and these two comparisons give significantly different results.

So far, all observations and analyses of the SMMF have been carried out using spectral lines formed at the photosphere. In this paper, we use the Ca II 8542 Å spectral line to calculate the SMMF of the chromosphere and photosphere. We validate our photospheric SMMF calculations by comparing them with available SMMF values from reference instruments and proceed to compare photospheric and chromospheric SMMF values.

2. The Data

2.1 *Data description*

The primary instrument used for data in this paper is the SOLIS - Vector Spectromagnetograph (VSM) (Keller & Solis Team, 2001; Keller *et al.*, 2003). SOLIS stands for Synoptic Optical Long-term Investigations of the Sun. It is a telescope facility with three instruments, VSM being one of them. SOLIS has been offline since October 22, 2017, as it is being relocated and installed at the Big Bear Solar Observatory (BBSO), California.

VSM is a Ritchey-Chrétien telescope fitted with a grating spectropolarimeter. [1] It has multiple modes of observation, among which we are interested in the 6302L and 8542L modes, which provide the full-disk, line-of-sight (LOS) magnetograms of the Sun at Fe I 6301.5 Å and Ca II 8542 Å, respectively. Samples of the 6302L and 8542L magnetograms are shown in Figure 1. Here, the 6302L data contains one magnetogram while the 8542L data contain two magnetograms; one generated using the core

of the Ca II 8542 Å spectral line [8542.1 Å ± 600 mÅ: hereafter called line-core data], and the other generated using the wings of the Ca II 8542 Å spectral line [8540.1 Å - 8541.5 Å, 8542.7 Å - 8544.1 Å: hereafter called line-wings data][2]. New CCD cameras added in January 2010 improved the spatial sampling of these magnetograms to 1 arcsec pixel^{-1}. Using these magnetograms the SMMF values are calculated.

The 6302L mode takes 20 minutes to generate the magnetogram, while the 8542L mode takes 40 minutes for the process. The magnetograms are generated daily, sometimes twice a day. The observed LOS magnetograms, after relevant geometric and intensity corrections, are made available as Level 2 FITS files[3]. We have used these files from 2010 May 1 to 2017 October 21 in our analyses.

The daily mean magnetic field data from the Wilcox Solar Observatory (WSO) at Fe I 5250 Å photospheric line is considered the reference for SMMF calculations. This data is available from 1975 onwards[4]. Kutsenko & Abramenko (2016) compared the WSO mean magnetic field to the SMMF calculated from full-disk magnetograms of the Helioseismic and Magnetic Imager (HMI) (Scherrer *et al.*, 2012) onboard the Solar Dynamics Observatory (SDO), and found a conversion factor of 0.99. The HMI has better precision, faster cadence data than WSO. This prompted us to use HMI SMMF measurements also to validate VSM SMMF values. HMI is a filtergraph that observes the Sun at the Fe I 6173 Å photospheric line. Among other data products, it provides full-disk LOS magnetograms at a cadence of 720 seconds. A sample magnetogram is shown in Figure 1. We use the corresponding Level 1.5 science-ready data and the WSO mean field data, both taken during the same period as the VSM data, in our analyses.

We also use sunspot numbers in this paper to identify different stages of the solar cycle such as solar maximum, solar minimum, etc., and to study the variation of the SMMF with respect to the solar cycle. Sunspot numbers are made available by the Sunspot Index and Long-term Solar Observations (SILSO), which is an activity under the Solar Influences Data analysis Center (SIDC), Royal Observatory of Belgium, Brussels.

Instrument	Data	Spectral line	Method
WSO	Mean Field	Fe I 5250 Å	Zeeman splitting
HMI	M_720s (level 1.5)	Fe I 6173 Å	Doppler shift
VSM	6302L (level 2)	Fe I 6301.5 Å	Zeeman splitting
VSM	8542L line-core (level 2)	Ca II 8542 Å	Zeeman splitting
VSM	8542L line-wings (level 2)	Ca II 8542 Å	Weak field approximation

Table 1: Instruments and spectral lines used to calculate SMMF in this work, and the method of calculation of magnetic field.

2.2 *Details of magnetic field calculation and a review of comparison of data from different sources*

A summary of the sources and details of the various datasets used in this work are given in Table 1. The VSM spectrograph works in Littrow mode, and scans the solar disk from solar south to solar north, with its slit in the solar east-west direction (Keller *et al.*, 2003). In the 6302L mode, the magnetic flux density is calculated from Zeeman splitting, using a variant of the center-of-gravity method (Jones *et al.*, 2002). This mode has a spectral resolution of 23 mÅ (Pietarila *et al.*, 2013). In the 8542L mode, the magnetic flux density is calculated using the Weak Field Approximation (WFA)[5] (Egidio Landi Degl'Innocenti, 2004). For this purpose, the spectral line is divided into bins of size 37.5 mÅ, and the magnetic flux densities estimated from all bins are averaged[6]. The use of WFA in the line-core introduces a systematic deviation in the measured magnetic field from the actual value at field intensities above ≈ 1200 gauss (Centeno, 2018). However, the pixels with magnetic field > 1200 gauss occupy a very small fraction of the solar disk, and calculating the SMMF cancels out this deviation to some

extent. This fraction was calculated to be 6.8×10^{-6} for line-core data and 5.1×10^{-5} for line-wings data in an 8542L magnetogram taken during solar maxima (2015/Feb/05). The maximum value of instrumental noise is ≈ 3 gauss pixel^{-1} in both modes (Pietarila *et al.*, 2013).

The WSO uses a Babcock magnetograph with a grating spectrograph in the Littrow mode. To obtain mean magnetic field data, the solar image is formed slightly above the spectrograph slit, thus feeding integrated light to the spectrograph. The measurement error of the mean field is less than 0.05 gauss (Scherrer *et al.*, 1977b). The LOS magnetic field is calculated using the Zeeman splitting of the Fe I 5250 Å photospheric line, from the change in intensity of the oppositely polarised parts of the spectral line, where the profile is steepest (Babcock & Babcock, 1952; Beckers, 1968). Different authors give different multipliers for correcting the WSO magnetic field: $4.5 - 2.5 \times \sin^2 \delta$ (Wang & Sheeley, 1995), 1.85 (Svalgaard, 2006), no correction (Riley *et al.*, 2014). We have followed the latter and have not used any correction for the WSO data.

HMI uses a set of Lyot filters along with two Michelson interferometers to generate filtergrams. It samples the spectral line at 6 wavelength points separated by 69 mÅ. The LOS magnetic field is calculated from the Doppler velocities obtained from these filter-

[6]'SOLIS VSM 8542L full-disk images' at `https://nispdata.nso.edu/webProdDesc2/selector.php`

grams at different polarisations. The filter's effective FWHM is 76 mÅ and the random noise for this data is ≈ 6.3 gauss pixel^{-1} (Schou *et al.*, 2012; Liu *et al.*, 2012).

Pietarila *et al.* (2013) analyzed the magnetic flux densities measured from VSM and HMI magnetograms, and found that they are comparable. They also calculated a linear fit of $MDI = -0.18 + 0.71 \times VSM$ by comparing the mean magnetic field between VSM and MDI. Since MDI and HMI values are very much identical, our comparison of the HMI and VSM SMMF should give similar results. Kutsenko & Abramenko (2016) compared the WSO mean field and the disk-integrated magnetic field from HMI, and found a linear regression fit of $HMI = 0.99 \times WSO$ and a Pearson correlation coefficient of 0.86. We would expect to get the same values from our analysis. Similarly, inter-instrument comparisons of the magnetic field and SMMF at different spectral lines have been made by multiple authors. So, despite the differences between instruments and spectral lines used for observations, we see that a comparison of the SMMF is quite plausible. The heights of formation of these spectral lines are analyzed in the next subsection, to understand which pairs of spectral lines form at same heights in the solar atmosphere.

2.3 *Response functions of the spectral lines*

A response function provides the response of a spectral line to variations in atmospheric parameters. Response functions are partial derivatives of a physical parameter (X) with height ($RF_X(h, \lambda) = \delta I(\lambda)/\delta X(h)$) (Beckers & Milkey, 1975). They are calculated by providing "+" and "−" perturbations (Δx) to the atmospheric parameter at each height and synthesising the spectral line profile, S^+ and S^-, respectively. The response of the physical parameter at each height is then given by

$$RF_X(h, \lambda) = \frac{S^+ - S^-}{2 * \Delta x} \qquad (1)$$

We calculated the response functions of the following lines in the context of our analyses: Fe I 5250 Å , Fe I 6173 Å , Fe I 6301.5 Å and Ca II 8542 Å . Please refer to these resources for similar calculations: Quintero Noda *et al.* (2021); Bellot Rubio *et al.* (1997); Quintero Noda *et al.* (2016). For our calculations, we used the atmospheric model FAL-C (Fontenla *et al.*, 1993) which represents the quiet Sun, and introduced magnetic fields of intensity [50, 200, 500, 1000, 2000, 3000] gauss. The response of the Stokes V profile to the perturbations in the LOS magnetic field, averaged over the above magnetic fields, are presented with respect to height in Figure 2.

We observe that the response functions of the Fe I lines are very similar in shape. Nevertheless, the Fe I 5250 Å line peaks at ≈200 km above the surface, whereas the Fe I 6301.5 Å line peaks at ≈100 km above the surface. The Fe I 6173 Å line has peaks at both ≈100 km and ≈200 km above the surface. The plots also indicate that the Ca II 8542 Å line has contributions from both the photosphere and the chromosphere. We observe that its line-core (± 600 mÅ from the line-center) has contribution only from chromospheric heights (500 km above the surface is the temperature minimum region in the FAL-C model), and its line-wings (± 2 Å, excluding the line-core) have contribution only from upper photospheric heights. Thus, we infer that the radiation from the wings of the Ca II 8542 Å line is originating from the upper photosphere, and the radiation from the core of the Ca II 8542 Å line is originating from the chromosphere.

2.4 *Data selection*

One magnetogram per day is considered for our analysis. In general, the 6302L and 8542L data differ in their observation times. We considered only the data for which both observations were taken within 2 hours of each other. This accounted for 88% of all observations taken during the above stated period. There was usually only one magnetogram available in a day, sometimes 2–3. If more than one magnetogram satisfied the 2-hour condition, the earliest among them was selected. If there were no magnetograms in a day that match the 2-hour condition, no datapoint was taken for that day. There are 1506 days of observation satisfying this criterion, each day having one magnetogram each from 6302L, 8542L line-core, and 8542L line-wings data.

It was observed that there are pixels in the VSM magnetograms having values of *Not-A-Number (nan)* or *zero*. These could have come during the acquisition or processing of the data. Unaffected data always has a floating point value. We termed such pixels containing either *nan* or *zero* values as bad pixels. Sample magnetograms with bad pixels are shown in Figure 3a. We observed that many of the bad pixels appeared as bands of missing data in magnetograms and that the width of these bands increased as the fraction of bad pixels in the solar disk increased. We decided to discard magnetograms with bands of size ≥ 20 arcseconds. This corresponded to 0.45% or more of the solar disk covered by bad pixels. When one magnetogram among the three modes (6302L, 8542L line-core, 8542 line-wings) was discarded, the others were discarded too. These corresponded to 41 days of data (datapoints). Apart from the above bad pixels, some magnetograms were observed to have artifacts shaped as stripes across the solar disk (Figure 3b). These magnetograms were also discarded,
Figure 2: The response of the Stokes V profile to the perturbations in the LOS magnetic field, averaged over different magnetic fields, are presented with respect to height

for the spectral lines (a) WSO Fe I 5250 Å [5250.216 Å ± 100 mÅ], (b) HMI Fe I 6173 Å [6173 Å ± 250 mÅ], (c) VSM Fe I 6301.5 Å [6301.515 Å ± 0.5 Å], (d) VSM Ca II 8542 Å line-wings [8540.1 Å- 8541.5 Å, 8542.7 Å- 8544.1 Å], (e) VSM Ca II 8542 Å line-core [8542.1 Å ± 600 mÅ]. The functions are calculated at multiple points in the instrument's wavelength range, and at the magnetic field values [50, 200, 500, 1000, 2000, 3000] gauss, and averaged. The red dotted line shows the peak of the response function for the WSO Fe I 5250 Å line.

leaving 1459 datapoints.

Once the magnetograms were selected, for each magnetogram (say 6302L), the bad pixels were located and *nan* value was assigned to the pixels at the same locations in its complementary magnetograms (8542L line-core and line-wings). This was repeated for each of the 8542L magnetograms. This makes sure that the magnetograms are comparable. All magnetograms (6302L, 8542L line-core, and 8542L line-wings) are already North-corrected in Level 2. The solar center changes by less than a pixel between corresponding 6302L/8542L files; this difference is neglected. For each magnetogram, a circular mask centered at the solar center and with a radius equal to 99.5% of the solar radius was generated to select the solar disk. The solar disk boundary was avoided because of the sharp change in intensity. The values of the solar center and solar radius were read from the corresponding FITS header. The arithmetic mean of all pixels within this mask was calculated and recorded as the Solar Mean Magnetic Field (SMMF).

Similarly, for each HMI magnetogram a mask was created and the arithmetic mean of the pixels within this mask was recorded as the SMMF. We used two parameters in the header file to select HMI data - QUALITY and QUALLEV1. They are non-zero for calibration data, and also when the data is not good. We excluded all data with non-zero values of either of these two parameters, and random checking of the selected magnetograms showed that *nan* values were absent in the

(b)
Figure 3: (a) Sample VSM magnetograms that have many bad pixels. Intensity thresholding is [-5, 5] gauss. (b) A sample VSM magnetogram that has artifacts shaped as stripes. Intensity thresholding is [-60, 30] gauss.

solar disk. 1267 magnetograms were selected by this process, which were all taken within 2 hours of VSM observations.

We define SMMF (6302L) as B_p, SMMF (8542L line-wings) as B_w, SMMF (8542L line-core) as B_c, SMMF (WSO) as B_{wso} and SMMF (HMI) as B_{hmi}. The average observation times of corresponding 6302L and 8542L datapoints were calculated, and the SMMF values were associated with them to facilitate comparisons.

2.5 *Data validation*

The *VSM photospheric mean net flux* is a dataset present in the SOLIS website[7]. Each datapoint in this dataset corresponds to a magnetogram, and has the average value of all pixels within 99% of the solar disk. B_p compares well with this mean net flux. Choosing datapoints observed at the same time (since the latter could have multiple datapoints/day), we get 1489 common datapoints between them, which yield a linear regression coefficient (β) of 0.99 (B_p v/s net flux) and a correlation coefficient (γ) of 0.99. This confirms the accuracy of our calculation of B_p.

Similarly, each of the HMI magnetograms' FITS header file contains a parameter called DATAMEAN, which is equal to the disk-averaged flux. We compared B_{hmi} with the value of the DATAMEAN parameter. They matched very well, with $\beta = 0.98$ (B_{hmi} v/s DATAMEAN) and $\gamma = 1.00$. This corroborates our calculation of B_{hmi}.

However, we have not used either the VSM photospheric mean net flux or the HMI DATAMEAN parameter as the SMMF. This is because, the DATAMEAN parameter is calculated for all magnetograms, whether they are calibration files, observation files or erroneous files, and the VSM photospheric mean net flux is calculated for magnetograms with erroneous data (artifacts) also. As mentioned in the previous subsection, we have discarded such erroneous data.

2.6 *Data analysis*

The plots of daily VSM SMMF, B_{wso}, B_{hmi}, and sunspot numbers (13-month running average, and monthly running average) are shown in Figures 4, 5. B_p, B_c and B_w are plotted according to their average observation times. Each datapoint is shown by a dot, whereas lines connect adjacent datapoints. Data gaps can be understood by the absence of dots in the line. The VSM data has 1267 common datapoints with B_{hmi}, and 1241 common datapoints with B_{wso}. B_p, B_w and B_c have 1459 common datapoints. The vertical blue

| | γ | | | |
	B_p	B_w	B_c	B_{hmi}
B_{wso}	0.89	0.87	-	0.86
B_{hmi}	0.95	0.92	-	-
B_p	-	0.92	-	-
B_w	-	-	0.80	-
	β			
	B_p	B_w	B_c	B_{hmi}
B_{wso}	1.56	1.84	-	1.09
B_{hmi}	1.30	1.53	-	-
B_p	-	1.13	-	-
B_w	-	-	0.60	-

Table 2: Correlation coefficients (γ) and linear regression coefficients (β) between B_{wso}, B_{hmi}, B_p, B_c and B_w, calculated over the entire observation period from 2010 to 2017. How to read the table: for the linear regression coefficient, the parameter in the first column is the independent variable, and the parameter in the row is the dependent variable.
lines demarcate different stages of the solar sunspot cycle, such as solar minimum, rising phase, solar maximum, and declining phase. This has been done using the 13-month running averaged sunspot number from SILSO.

A visual inspection of Figures 4, 5 show that VSM SMMFs, B_{wso}, and B_{hmi} are similar in shape, but have differences in their amplitudes. Correlation and regression coefficients between the SMMF data for the complete observation time are presented in Table 2, and the scatter plots for the same are given in Figure 6. We also calculated these coefficients within each stage of the sunspot cycle (mentioned above), but did not observe any patterns. They were also calculated according to the 13-month running averaged sunspot numbers, during periods of low solar activity (count < 50, 40, 30, 20), and high solar activity (count > 50, 60, 70, 80, 90, 100, 110). These results are mentioned in Table 3. From this table, we observe that the correlation between B_w and B_c is higher at periods of low solar activity (lower sunspot numbers) compared to periods of high solar activity (higher sunspot numbers).

We also compared B_{hmi} with B_{wso} during the entire VSM observation period (1115 datapoints), and found $\gamma = 0.86$ and $\beta = 1.09$ (HMI v/s WSO). We note that the value of γ is exactly same as that of Kutsenko & Abramenko (2016), while there is a slight difference in the value of β; this could be because of a few reasons. Kutsenko & Abramenko (2016) had used 1507 data pairs between January 1, 2011 and December 10, 2015 in their analysis. So, one possibility is that the two

the HMI level 1.5 data, and although we assume that the former authors have used the same level of data, it's not mentioned in their paper.

3. Results and Discussion

We have used both B_wso and B_hmi as references in our calculations. As mentioned in section 2, the HMI data has better precision compared to WSO. We can notice this in Figure 5, where periodicities during the first half of 2017 are hard to notice in B_wso, whereas visible in B_hmi. But, B_hmi data is only available from 2010 May 1 onwards. Thus, we have used both B_wso and B_hmi in this study. We have tabulated the correlation (γ) and linear regression (β) coefficients between the VSM SMMF datasets and the reference datasets (B_wso and B_hmi), and also within the VSM SMMF datasets. The response functions of VSM Fe I 6301.5 Å line, WSO Fe I 5250 Å line, and HMI Fe I 6173 Å line are similar in shape, i. e., these spectral lines have similar heights of formation, and similar contributions from each height of the solar atmosphere. Thus, they probe a similar region in the solar atmosphere. This, coupled with the good correlation of the associated SMMF datasets, leads us to consider β to be the scaling factor between these datasets. The scaling factors are as follows: $B_\mathrm{p} = 1.56 \times B_\mathrm{wso}$, $B_\mathrm{p} = 1.30 \times B_\mathrm{hmi}$. However, the response function of the VSM Ca II 8542 Å line-wings peaks at a different height and has different contributions from atmospheric heights compared to the former response functions. Thus, β cannot be considered as the scaling factor between these datasets.

B_c and B_w have $\beta = 0.60$. Since both measurements are taken from the same instrument using the same procedure, no further calibration is needed. It directly gives the conversion factor of chromospheric SMMF to photospheric SMMF. $\beta < 1$ implies a reduction in intensity from the photospheric SMMF to the chromospheric SMMF. We also note that $\gamma = 0.80$ between B_w and B_c, and that it is higher at periods of low sunspot numbers as compared to periods of high sunspot numbers. But, as mentioned in section 2.2, the WFA underestimates the magnetic field at high field intensities. As helpfully mentioned by our referees, this could result in improved correlation at periods of low magnetic field (low sunspot numbers). To verify this possibility, we calculated the correlation coefficients between the SMMF datasets using pixels with magnetic field < 1200 gauss, and found that there is no effect of WFA on the correlation. A drawback in this study is that since B_w has contribution only from upper photospheric heights, we are not having information from all heights of the photosphere. This is related to the

wavelength range (600 mÅ - 2 Å from the center of the spectral line) which is available as Ca ɪɪ 8542 Å linewings data. So, a future work could be to consider different wavelength ranges (further away from the linecore), check their Stokes-V response functions, and select the one which has a contribution from all photospheric heights.

4. Conclusion

In this paper, we have calculated and compared the photospheric (B_p and B_w) and chromospheric (B_c) SMMF values estimated from VSM full-disk magnetograms. We used the mean field data from WSO (B_{wso}) and HMI (B_{hmi}) as references to validate the VSM SMMF values and observed that the SMMF values between different instruments retain similar features but differ in their magnitudes. We note that the difference in values between VSM and WSO/HMI could be because of the instrument conversion factor. On the other hand, the comparison between VSM 8542 line-core (chromospheric SMMF) and line-wings (upper photospheric SMMF) does not contain any effects of the instrument or measurement techniques, and their linear regression coefficient can be considered as the ratio of the SMMF at these heights. It was found that the chromospheric SMMF is weaker by a factor of 0.6 compared to that of upper photospheric SMMF. This reduction in intensity could mean that a significant part of the SMMF is a magnetic field that propagates outwards from the photosphere to the chromosphere. This is in line with the view that the SMMF could have a source, decoupled from solar activity. It was also found that the correlation between B_c and B_w is higher during periods of lower solar activity. The similarity between the photospheric and chromospheric SMMFs, and the reduced intensity of the chromospheric SMMF with respect to the photospheric SMMF corroborate the idea that the SMMF could be passing through the photosphere, chromosphere, and arriving at interplanetary space, where we measure it as the IMF.
